STI Working Paper Series

The Working Paper series of the OECD Directorate for Science, Technology and Industry is designed to make available to a wider readership selected studies prepared by staff in the Directorate or by outside consultants working on OECD projects. The papers included in the series cover a broad range of issues, of both a technical and policy-analytical nature, in the areas of work of the DSTI. The Working Papers are generally available only in their original language – English or French – with a summary in the other.

Comment on the papers is invited, and should be sent to the Directorate for Science, Technology and Industry, OECD, 2 rue André Pascal, 75775 Paris Cedex 16, France.

The opinions expressed in these papers are the sole responsibility of the author(s) and do not necessarily reflect those of the OECD or of the governments of its Member countries.

**IMPACT OF THE ADOPTION OF ADVANCED INFORMATION AND COMMUNICATION
TECHNOLOGIES ON FIRM PERFORMANCE IN THE CANADIAN MANUFACTURING
SECTOR**

**John R. Baldwin
David Sabourin***

Abstract

This paper investigates the evolution of the industrial structure in the Canadian manufacturing sector and its relationship to technological change by examining the take-up of advanced technologies and how it is related to the stochastic growth process in the plant population. Its framework is grounded in the view that growth is a stochastic process that involves learning. Experimentation with new technologies rewards some firms with superior growth and profitability. Examining how growth is associated with the choice of different technology strategies indicates which of these is being rewarded.

The evolution of this process is studied by examining the relationship between the uptake of advanced technologies and the performance of plants in the manufacturing sector. This is done by using cross-sectional data on advanced technology use and by combining it with longitudinal panel data on plant performance. In particular, the paper examines the relationship between the use of information and communication technology (ICT) and the growth in a plant's market share and its relative productivity.

The study finds that a considerable amount of market share is transferred from declining firms to growing firms over a decade. At the same time, the growers increase their productivity relative to the decliners. Those technology users that were using communication technologies, or that combined technologies from several different technology classes, increased their relative productivity the most. In turn, gains in relative productivity were accompanied by gains in market share. Other factors that were associated with gains in market share were the presence of research and development (R&D) facilities and other innovative activities.

Résumé

Le présent document s'intéresse à l'évolution de la structure industrielle du secteur manufacturier au Canada de même qu'à son lien avec le changement technologique en examinant l'adoption de technologies de pointe et son rapport avec le processus de croissance stochastique dans la population des usines. Il s'articule autour du point de vue selon lequel la croissance est un processus stochastique dans lequel intervient l'apprentissage. L'expérimentation des nouvelles technologies récompense certaines entreprises à croissance et à rentabilité supérieures. Pour savoir lesquelles, on y examine le rapport entre la croissance et le choix de différentes stratégies technologiques.

Le document étudie l'évolution de ce processus en sondant la relation entre l'adoption de nouvelles technologies et la performance des usines dans le secteur manufacturier; cela se fait par la combinaison de données transversales sur les technologies de pointe à des données de panel longitudinales sur la performance des usines. Il s'intéresse en particulier au lien entre l'utilisation des technologies de l'information et des communications (TIC) et la croissance de la part de marché et de la productivité relative d'une usine.

Il apparaît qu'une proportion considérable de la part de marché passe des entreprises en déclin aux entreprises en croissance sur une période de dix ans. En même temps, les secondes augmentent leur productivité par rapport aux premières. Les utilisatrices de technologies qui employaient des technologies de communication ou combinaient différents types de technologies à partir de diverses catégories de technologie ont accru le plus leur productivité relative. Ces hausses de la productivité relative se sont accompagnées d'élargissements de la part de marché. Ont aussi contribué à accroître la part de marché la présence d'installations de la recherche et du développement (R-D) et d'autres activités innovatrices.

Introduction

This paper investigates the evolution of industrial structure in the Canadian manufacturing sector and its relationship to technological change by examining the take-up of advanced technologies, and how it is related to the stochastic growth process in the firm population. Its framework is grounded in the view that growth is a stochastic process that involves learning. Production opportunities are not unique and the growth of individual firms occurs in a world where each explores which advanced technologies out of a set of many technological possibilities might be the most suitable to its circumstances. Firms adopt new, advanced technologies as they learn about their possibilities and experiment with their applicability to their own specific situations. Experimentation rewards some firms with superior growth and profitability.

A range of new advanced technologies is available at any point in time. Not all firms will choose the same set. Nor will a particular set result in equal rewards across all environments. The environment faced by a firm and the history of the firm determine the end results of experimenting with new technologies. What may be “best practice” is difficult for firms to ascertain *ex ante* and only evolves as the selection process demonstrates which firms have made the “correct” decision.

New technologies are adopted slowly into the production process because the amount of learning by experimentation is large. A large number of complementary machines and production processes have to be put in place before new technologies can find useful applications.¹ And finding the correct combination requires considerable trial and error. Mature technologies can be incorporated into the production process with the use of blueprints. When knowledge is readily codifiable and easily transferred from one firm to another, diffusion is rapid. By way of contrast, the introduction of new technologies during the early phases of an industrial transformation is more akin to prototype construction. Plans are used as the foundation for a prototype, but the construct changes over time as experience dictates needed changes. Search takes place through a learning-by-experimentation process.

This paper describes how this process evolves by examining the impact of advanced technology adoption on the performance of plants in the manufacturing sector by using cross-sectional data on advanced technology use and by combining it with longitudinal panel data on plant performance.

It focuses on technologies associated with the information and communication technology (ICT) revolution. The relatively cheap processing power of microchips has brought about a dramatic technological change in the manufacturing sector. On the one hand, these consist of a number of labour-saving technologies where computer-assisted machinery has been developed to replace manual labour. For example, computer-operated robots provide an efficient and safe alternative to humans for repetitive jobs like spot welding and painting. Automated guided vehicle systems replace costly personal delivery. However, the truly dramatic element of the IT revolution has been the birth of “soft manufacturing”, which Bylinsky (1994) notes, differs from traditional manufacturing in that software and computer networks are more important than production machines. Furthermore, Bylinsky argues that the effect of the “soft-manufacturing” technologies has been to enhance rather than replace the abilities of workers. Flexible manufacturing systems with the agility to provide information quickly to workers and to management allow for a high degree of customisation at a much lower cost than in the past. The IT revolution has allowed plants to deliver customised products in small quantities, allowing them to change product lines quickly to meet changing consumer demands.

1. See Baldwin and Sabourin (2000) for a study of the importance of advanced engineering practices for advanced technology adoption.

The first section of the paper examines certain characteristics of the stochastic process that are relevant to the measures of firm and plant performance used in this paper. It enumerates the extent to which plants replace one another by transferring market share from one to another over the ten-year period 1988 to 1997, and the extent to which this has been accompanied by changes in relative productivity and profitability.

The paper then studies the effect of technological change on productivity. It examines the relationship between the use of advanced manufacturing technology, such as programmable controllers, local area networks and computer-aided design and engineering equipment, and plant performance. This allows us to discern whether the technological choices are associated with growth. Not all plants have adopted new computer-based advanced technologies. We examine the relationship between changes in plant market share and relative productivity over the time period and the advanced technologies that plants manage to successfully implement by 1998 – showing whether plants using advanced technologies, in effect, are selected for survival and growth by the search and culling process that is associated with competition.

The economic performance data used in the study come from a longitudinal file developed from the Annual Survey of Manufactures, which includes data on employment (production and non-production), labour productivity (value added per worker), wages and salaries, manufacturing and total shipments, and manufacturing and total value added for Canadian manufacturing plants during the period 1988-97.² The economic performance data were linked to data on advanced technology use at the plant level derived from the 1998 Survey of Advanced Technology in Canadian Manufacturing. In what follows, we will be using plants as the unit of analysis.

The growth process

Growth and decline take place as some plants wrest market share away from others. The amount of change in the manufacturing sector is large. Over the period 1988-97, some 47% of market share is transferred from those losing market share to those gaining market share within a four-digit industry, on average. Growing continuers account for 26 percentage points of the gain in market share, while entrants account for the other 21 percentage points. Decline in market share, on the other hand, comes from declining continuers (17 percentage points) and exits (30 percentage points).

This turnover is made up of a large number of small changes, with many new firms seizing small amounts of market share and many incumbents growing slightly at the expense of others. At the same time, there are a large number of exits, most of which are quite small, and many incumbents who also decline. In the short run, much of this change is reversed – but in the longer run, over periods of a decade, the changes lead to substantial shifts in the relative rankings or position of industry participants.

The extent to which plant growth and decline leads to changes in relative rankings is presented in Table 1. Plant market shares at the four-digit level are calculated for 1988 and for 1997 and then all establishments are assigned to quartiles in both the start year (1988) and the end year (1997) of the period, based on the rankings of their market share. Table 1 provides the movement of continuing establishments up and down the market-share hierarchy. It gives the percentage of continuing plants who started in a given quartile in 1988 that had moved up or down a quartile or two, or stayed in the same quartile.

2. Total value added differs from manufacturing value added because of non-manufacturing activities of manufacturing establishments that are intrinsic to the manufacturing operations of the firm.

Throughout the decade, there has been substantial change in relative status. For example, of those continuing plants that were in the second quartile in 1988, 23% fell to the bottom quartile in 1997; 17% moved up to the third quartile; while 57% remained in the same quartile.

Table 1. **Market-share transition matrix for continuers, 1988-97¹**

Market-share quartiles (1988)	Market-share quartiles (1997)			
	Q1	Q2	Q3	Q4
	Percentage of establishments			
Q1	82	15	3	0
Q2	23	57	17	2
Q3	2	22	60	16
Q4	2	2	13	83

1. In table 1, the quartiles are calculated using all establishments, but the shares are calculated only for continuers.

There is somewhat greater inertia in the plants that started in the bottom or top quartile – partially because their movement possibilities are truncated, either in an upwards direction for the top quartile or downwards for the bottom quartile. Over 80% of the plants in these two groups remained in the same quartile group. Close to a fifth moved to the adjoining category.

Success in terms of the growth in market share is accomplished in various ways. Plants may either improve their relative cost structure or may be able to produce higher-quality products for which consumers are willing to pay higher prices. In either case, we would expect this to be reflected in higher levels of labour productivity relative to the industry mean. Indeed, the gain in market share is accompanied by a growth in relative labour productivity. If we divide continuing plants into two equal groups based on market-share changes, we find that the relative labour productivity of gainers is equal to that of decliners at the start of the period (Table 2). Initial productivity in the continuing group is, therefore, not a good predictor of subsequent market-share performance. However, over the period, those gaining market share simultaneously manage to increase their relative productivity. By 1997, their relative productivity is 23% above that of the declining group. By the end of the period, the market has rewarded those who have managed to improve their efficiency or the quality of their product, and concomitantly their labour productivity, with an increase in market share.

Table 2. **Mean relative labour productivity for high-market-share gainers/decliners and low-market-share gainers/decliners**

Market-share change (1988-97)	Relative labour productivity (RLP)		Δ RLP 1988-97
	1988	1997	
Two category scheme			
• Low gainers or decliners (median and below change)	1.002	0.867	-0.135
• High gainers (above median change)	0.998	1.078	0.080

The amount of change in relative labour productivity can be investigated using the same type of transitions matrix that was applied to market-share changes. Labour productivity is defined here as total value added divided by total employment. It is calculated for each plant relative to its industry's labour productivity. Changes in relative labour productivity will occur as a plant becomes more efficient or if it increases its use of capital and other inputs relative to other plants in the industry.

The transition matrix for the relative labour productivity of continuing plants between the years 1988 and 1997 is provided in Table 3. Ranking establishments according to their relative labour productivity in each of 1988 and 1997, and assigning them to quartiles in each of the two years, the transition matrix provides the percentage of establishments that had bettered their relative position, stayed the same, or declined. Relative labour productivity is calculated for the four-digit industry in which it is located for both years.

As evidenced by Table 3, there is a large amount of shifting of relative position. For continuers, half of the plants shifted up from the lowest quintile and half shifted downward out of the top quintile. Half of the plants initially in the top and bottom quartiles remained there by the end of the period. For those in the middle two quartiles, the movement was even greater, with only a third still in the same quartile in which they had started.

Table 3. Relative labour productivity transition matrix for continuers, 1988-97

Relative labour productivity quartiles (1988)	Relative labour productivity quartiles (1997)			
	Q1	Q2	Q3	Q4
Percentage of establishments				
Q1	49	23	18	10
Q2	28	33	24	15
Q3	15	29	31	25
Q4	9	12	28	51

While the preceding discussion has focused on the continuing population of establishments, the role that entrants and exits play should not be ignored. Figure 1 depicts the percentage of new plants that fall into each of the market-share quartiles and productivity quartiles in 1997. Figure 2 does the same for the closed plants using the 1988 quartiles.

We find that new establishments are roughly equally distributed across relative productivity quartiles by the end of the period, although to a slightly lesser extent for the highest quartile (Figure 1). A similar, although less pronounced, pattern emerges when market share is considered. More than 40% of establishments born in the 1988-97 period, and that are still alive by the end of the period, are in the top two quartiles by 1997. In fact, 17% of entrants actually find themselves in the highest quartile group. In other words, surviving entrants, when examined over a ten-year period, do not remain at the bottom end of the size distribution.³

Exits of the 1988 population that disappear by 1997 also come from all quartiles of the 1988 size distribution (Figure 2), although the smallest are most likely to exit. The percentage of each 1988 market-

3. For additional Canadian evidence on the importance of entrants in this process, see Baldwin and Gorecki (1991), Baldwin (1995, Chapter 9), Baldwin (1996a).

share quartile that exits by 1997 varies from over 63% in the quartile with the smallest establishments to over 34% for the plants in the largest quartile. Exiting plants are slightly more likely to be found in the quartile that is less productive. Some 55% of establishments in the lowest productivity quartile had exited, compared to 38% of those in the highest quartile.

Success, innovation and advanced technology use

There are many factors behind the growth of firms and plants – ranging from overall management capabilities to marketing, human resources and operational capabilities. A substantial part of a firm's capital consists of these internal competencies. One branch of the business literature has focused on the extent to which there is a set of core competencies (Prahalad and Hamel, 1990). Another argues that one of the key areas for success is the dynamic capabilities of a firm that enable it to learn (Teece *et al.*, 1997). Dosi and Marengo (1994) emphasise that there are a variety of ways that firms can learn and that this learning is tied to different sources of technological capabilities. These capabilities extend beyond R&D performance to encompass those activities that enable a firm to ingest new information and to act quickly and effectively on it. In turn, advantages in this area are postulated to be associated with different levels of performance.

Figure 1. **Productivity and market-share distributions for entrants over the 1988-97 period**

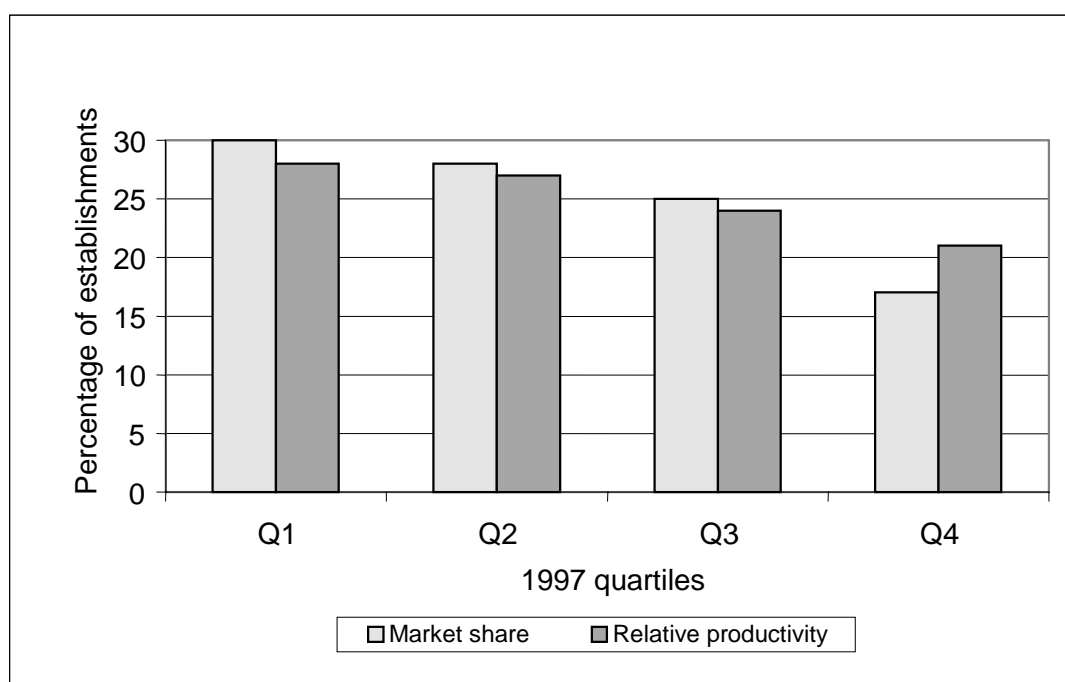

Figure 2. Productivity and market-share distributions for exits over the 1988-97 period

In three earlier studies (Baldwin, Chandler *et al.*, 1994; Johnson, Baldwin and Hinchley, 1997; Baldwin, Diverty and Sabourin, 1995), we have investigated the difference in the competencies found in growing and declining firms to see whether a key difference between the two lies in the nature of their innovation regime. These three studies use three different surveys as sources and find similar results in each case.

While growing firms have to do many things better in order to succeed, there is one factor that appears to discriminate best between the more-successful and the less-successful. Innovation is consistently a factor associated with successful growing firms (Baldwin, 1997; Baldwin and Johnson, 1998).

In the first study, the generally successful population of small and medium-sized firms (all firms in the study had positive growth over a five-year period) is divided into the more-successful and the less-successful firms and the characteristics of each are compared. This grouping is done using an overall measure of firm performance that is an average of three performance measures – market-share growth, labour productivity growth and profitability growth of a firm relative to other firms in an industry. The key characteristic that distinguished the two groups was the degree of innovation taking place in a firm (Baldwin, 1996b). The more-successful firms tended to place greater emphasis on R&D capability and R&D spending. They were more likely to give greater importance to developing new technology. In the production area, they gave more significance to using new materials, and implementing aggressive new strategies like process control and just-in-time inventory control. Differences in the emphasis that the two groups gave to R&D strategies were accompanied by differences in the intensity of R&D activities. More-successful firms were more likely to have an R&D unit. They were more likely to use R&D tax credits. They were also more likely to report that they used patents to protect their innovations.

The second study, the *Survey of Operating and Financial Practices (SOFP)* of entrants (Johnson, Baldwin and Hinchley, 1997) provides an overview of the competencies developed by new firms that survive into their teen years. It too is linked to data on sales and financial structure that provide measures

of performance for each survivor. As was found in the case of the study of growing small and medium-sized enterprises, success was closely related to innovation. Faster growing entrants were twice as likely to report an innovation. Faster growing entrants were more likely to invest in R&D and technology. They were also more likely to introduce new products. They were more likely to be targeting new foreign markets (Baldwin and Johnson, 1999). But faster growing firms were also more likely to be giving more emphasis to training, recruiting skilled employees and providing incentive compensation programmes (Baldwin, 2000).

The findings of the GSME and SOFP surveys as to the importance that firms gave to innovative strategies and activities, are confirmed by another study that uses data at the plant level on the use of advanced technologies. Advanced technology use is a form of innovation. The 1989 *Survey of Advanced Technology* outlines the extent to which plants in the manufacturing sector use advanced technologies in the different functional areas that each firm must master – in fabrication and assembly, in inspection and communications, in integration and control, and in design and engineering. Data from this survey on 1989 technology use are linked to the performance of plants during the 1980s. Performance is measured using information on a plant's sales, labour productivity and wage rates. Advanced technology using plants are then compared to plants not using advanced technologies as of 1988 in order to study whether the market share, the productivity and the wage rate had grown relatively faster in the former group (Baldwin, Diverty and Sabourin, 1995).

Advanced-technology-using plants increased their market share relative to plants that were not using advanced technologies. Growth in market share was higher for users of advanced technologies in the fabrication and assembly area than for most of the other functional areas. It was also relatively high for plants that were complex technology users; that is, for plants that combined advanced technologies from several of the functional groups (design, fabrication, communications, or integration and control).

Plants that managed to successfully incorporate advanced technologies into their production process by 1989 also saw their labour productivity increase relative to non-technology users during the previous decade when the adoption of advanced technologies was occurring. Those that used communications technologies or that integrated advanced technologies from several areas experienced the highest productivity growth rates. Accompanying this increase in relative labour productivity was a growth in the relative wage paid to production workers.

In summary, all three studies found that firms that managed to grow more quickly also *developed* certain innovative competencies that distinguished them from firms that grew less quickly. Differences in technological competencies had the same effect. That innovative and technological competencies are linked is not surprising. Some 53% of respondents to the 1993 Survey of Innovation and Advanced Technologies who had indicated that they introduced the advanced technologies did so in conjunction with the introduction of a product or process innovation.

The conclusions, based on Canadian empirical evidence, are confirmed by research that covers the experience of other countries. Stoneman and Kwon (1996), Rischel and Burns (1997), Ten Raa and Wolff (1999), and Van Meijl (1995) find a positive relationship between advanced technology use and superior firm performance.

On the basis of these studies, there is a strong presumption that advanced technology users in Canadian manufacturing as of 1999 should have had superior performance during the 1990s. In order to investigate whether the same type of relationship between market performance and advanced technology use existed in Canada during the 1990s, we will examine the connection between advanced technology use and the growth of plant market share or the growth in productivity in this period. Growth is defined as the change in market share over the period 1988-97 – a period of ten years prior to the survey date of 1998. In

order to correct for industry effects, growth was defined in terms of market share, as calculated at the four-digit 1980 SIC industry level. Similarly, plant productivity is calculated relative to its four-digit industry average. Productivity is defined as labour productivity⁴ and will be affected by changes in capital intensity and technological advances.

In what follows, we compare the performance of plants throughout the 1990s to their technological profile at the end of the period. We have seen that differences in the productivity performance of growers and decliners do not exist at the beginning of the study period but emerge over the period studied. This accords with a world in which firms experiment with alternate advanced technologies and the market rewards those who have chosen the correct technologies and managed to get them to work in the appropriate fashion. At the end of any period, productivity differences are evident between those who have managed to gain market share and those losing market share. For this reason, this study examines the differences in advanced technology use at the end of the period and the changes that have occurred in market share and changes in relative labour productivity over the previous time period.

This procedure will show whether advanced technology use is associated with improved performance. It cannot ascertain how changes in technology use affect performance. It is, of course, likely that changes in advanced technology use at the margin matter – although to ascertain how important the latter are, we need a longitudinal database that compares changes of advanced technology use over time. The latter is the subject of a separate study (Baldwin and Sabourin, 2002).

In this paper, we experimented with performance measures calculated over two different periods of time. The first covered a seven-year span from 1990-97. The second covered the ten-year span from 1988-97. Both yielded qualitatively the same results – but the results were more significant over the longer time period and are reported here. This bolsters our trust in the hypothesis that change occurs slowly – that the effects of using advanced technologies do not emerge immediately. Lags in the effect of the use of new advanced technologies exist because new machines have to be integrated into the production process. New techniques and business practices are often required if the new technologies are to be more successful. For example, concurrent engineering practices are needed if design and engineering advanced technologies are to be used successfully in plants.⁵ The introduction of advanced business practices involves organisational changes and takes time to implement.

Data source for advanced technology use

We focus in this paper on the adoption of a set of advanced technologies that are based on microelectronic computer technology. Computer-based technologies have penetrated all parts of the production process – from the design and materials planning stage, through the fabrication and assembly process, to the inspection and materials handling stage. They are also a key part of the communications process. While computers have stimulated the development of individual components, they are also key to integration and control of the various parts of the manufacturing process.

The effect of computers does not arise just from the ubiquitous stand-alone desktop. It is true that certain aspects of design and engineering depend on the stand-alone computer – but software is equally important here. Moreover, chips and computers are being increasingly imbedded into machines. Just as the electric motor moved from being a separate appendage located beside machines to being included in the

4. Defined as census total value added for manufacturing operations divided by total employment of both salaried and production workers.

5. The relationship between these practices and technology has been explored more fully in a recent study of technology use in the food-processing sector (Baldwin, Sabourin and West, 1999).

machine, computers are now an integral part of machinery such as robots and flexible manufacturing systems.

In this study, we make use of the results of the 1998 Survey of Advanced Technology in Canadian Manufacturing conducted by Statistics Canada to measure the extent to which advanced technologies have been integrated into the production process. The survey is based on a frame of Canadian manufacturing establishments drawn from Statistics Canada's Business Register. The sample was randomly drawn from a manufacturing establishment population that was stratified by industry and size. Excluded from the target population were food-processing establishments and plants with fewer than ten employees (Sabourin and Beckstead, 1999). The overall response rate to the survey was 98%.

In addition to questions on which technologies were being used, the survey asked respondents questions about general firm and establishment characteristics, whether research and development was being conducted, whether several advanced business practices were being used, the skill requirements needed for advanced technologies, as well as questions about the benefits and obstacles to the adoption of advanced technologies.

Twenty-six advanced technologies were listed on the survey – technologies that are applied in a wide range of functional areas. These range from computer-aided design used in design and engineering, to robots used in fabrication and assembly, to computer networks used as part of the communications and control function. For the purposes of this study, the advanced technologies covered in the survey are aggregated into three information and communication technology (ICT) groups – *i*) software; *ii*) network communications; and *iii*) hardware technologies. In our earlier study (Baldwin, Diverty and Sabourin, 1995), we found that plants using communication technologies did particularly well over the 1980s. In a recent study, Ten Raa and Wolff (1999) also found a positive relationship between ICT use and productivity growth. Van Meijl (1995) argues that this is mostly due to externalities associated with ICT adoption.

The ICT groups, their constituent advanced technologies, and their adoption rates are provided in Table 4. Eight advanced technologies belong to the software group: computer-aided design and engineering (CAD/CAE); CAD output to control manufacturing machines (CAD/CAM); modelling or simulation technologies; manufacturing resource planning (MRP); computer integrated manufacturing; supervisory control and data acquisition (SCADA); use of inspection data for manufacturing control; and knowledge-based software.

Five advanced technologies belong to the network communications group: electronic exchange of CAD files; local area network (LAN) for engineering or production; company-wide computer networks; inter-company computer networks; and digital, remote controlled process plant control.

There are ten advanced technologies in the hardware class: flexible manufacturing systems; programmable logic controllers; robots with and without sensing capabilities; rapid prototyping systems; part identification for manufacturing automation; automated storage/retrieval systems; automated vision-based systems used for inspection/testing; other automated sensor-based systems used for inspection/testing; and computers used for control on the factory floor.

Three of the 26 specific advanced technologies – lasers for materials processing; high-speed machining; and near-net shaped technologies – have been excluded from the analysis.

Table 4. Adoption of advanced information and communication technologies (ICT), 1998
Percentage of establishments using the technology

ICT	Specific technology	<i>In use</i>	<i>Standard error</i>

	• Part identification for manufacturing automation	18	1.0
	• Automated storage/retrieval system	5	0.6
	• Automated vision-based inspection/testing systems	11	0.8
	• Other inspection/testing automated sensor-based systems	13	0.9
• Computers used for control on the factory floor	31	1.3	

Similar rates of adoption are found for each of the three ICT groups. Sixty-five percent of manufacturing establishments use at least one of the eight software technologies listed on the survey; 59% use at least one of the five network communications technologies; while 57% use at least one of the ten hardware-based technologies.

Computer-aided design technologies dominate the software category. Close to half the plants have adopted at least one computer-aided design and engineering technology (CAD/CAE), with about a third using at least one CAD/CAM machine.

Plants use a variety of network communications advanced technologies – local area networks, company-wide networks and inter-company networks. The use of programmable logic controllers and factory control computers in the hardware group is reported most frequently.

For our comparisons of technology use and plant performance, advanced technology use will be measured in several different ways in this study. We use: *i*) incidence of use (the use of at least one advanced technology); *ii*) intensity of use (the number of advanced technologies adopted); and *iii*) measures of complexity of use (whether advanced technologies are being combined from more than one

category). Plants adopt, on average, two advanced software technologies, and about one and a half network communications and hardware technologies each (Table 5).

Table 5. Incidence and intensity of adoption of ICTs, 1998
Standard errors provided in brackets

ICTs	In use (percentage of establishments)	Number of technologies	Number of technologies in group
Software	65 (1.3)	1.97 (0.05)	8
Hardware	57 (1.4)	1.49 (0.05)	10
Communications	59 (1.4)	1.40 (0.04)	5
All	76 (1.2)	4.85 (0.12)	23

Performance and ICT use

At issue is the extent to which plants that exhibit different levels of success are found to use advanced technologies more or less intensively. We approach this question first with bivariate analysis that compares different measures of performance to advanced technology use, and then with multivariate analysis that regresses performance measures on advanced technology use and a number of other plant characteristics.

For both purposes, we relate performance over a period (1988-97) to advanced technology use at the end of the period (1998).

$$1) \Delta \text{PERF}_{t-\tau,t} = f(\text{Tech}_t)$$

where $\Delta \text{PERF}_{t-\tau,t}$ is the change in a plant's performance measured in various dimensions (relative productivity, market share, employment share, relative wage rates, relative profitability) over the period $t-\tau$ to t and Tech_t is a measure of advanced technology use at the end of the period in year t .

Since advanced technology use at the end of the period is just the sum of advanced technology use at the beginning of the period $\text{Tech}_{t-\tau}$ and the change in advanced technology use over the period, $\Delta \text{Tech}_{t-\tau,t}$, Equation 1 can be written as:

$$2) \Delta \text{PERF}_{t-\tau,t} = f(\text{Tech}_{t-\tau} + \Delta \text{Tech}_{t-\tau,t})^6$$

Economic performance is expected to be related to technology use at the start of the period and changes in advanced technology use over the period.

Performance over any period is posited to be a function of advanced technology use at the beginning of the period because there is a learning process involved with the introduction and use of advanced technology. Changes in labour productivity resulting from advanced technology adoption are, therefore, expected to occur slowly as plant managers learn how to use them in the most effective fashion. Since benefits or gains from the adoption of advanced technology are not realised immediately, there is a lagged effect of advanced technology use on performance. In addition, we expect that increases in advanced technology use during the period will affect relative performance over the period. While all benefits from the adoption of additional technologies will not be felt immediately, some will be.

6. The estimated coefficient from such an equation will be a weighted average of the coefficients that are attached to each of $\text{Tech}_{t-\tau}$ and $\Delta \text{Tech}_{t-\tau,t}$

Relative labour productivity is calculated as total value added divided by total employment for the establishment divided by the same measure calculated at the four-digit industry level. Growth in relative labour productivity is calculated as the difference between end-period relative labour productivity and start-period relative labour productivity.

Labour productivity is affected by many factors – by technical change in a plant, by its changing capital intensity, by organisational changes – all of which factor into a firm's success. Since all of these factors and, in particular, capital accumulation are associated with firm growth, we make use of this measure.

While some might prefer to see a total factor productivity measure rather than a labour productivity measure used for this analysis, because the former is widely perceived to better measure technical progress, it should be noted that the two measures are closely related. When the production function approximates a Cobb-Douglas, growth in labour productivity is equal to multifactor productivity growth plus the growth in the capital/labour ratio times capital's share (Baldwin, Beckstead *et al.*, 2001). As a result, empirical studies often find similar results using the two measures (Salter, 1966). The final argument in favour of using labour productivity is that measures of it are inherently more accurate than measures of total factor productivity.

Growth in market share is measured here as the total shipments produced by an establishment relative to total shipments at the four-digit industry level. Growth is measured as the difference between end- and start-period market shares.

Growth in relative profitability is calculated here in a similar fashion, only that profitability at the establishment level is calculated as the value of shipments less wages, salaries and materials all divided by the value of shipments.

Bivariate results of the relationship of economic performance and advanced technology adoption are provided in Table 6. Three separate measures of performance are used – growth in relative productivity (column I), growth in market share (column II) and growth in relative profitability (column III) over the period 1988-97. In each case, establishments are divided into two equal sized groups, those with more and those with less growth than the median. Then the differences in advanced technology adoption of the two groups are compared.

Table 6. Relationship between performance growth, 1988-97, and advanced technology adoption, 1998¹

Advanced technology adoption	Performance growth, 1988-97

Numbers of ICT						
• Software	1.9	2.3	1.8	2.5	2.0	2.3
• Hardware	1.4	1.8	1.4	1.9	1.4	1.9
• Communications	1.4	1.7	1.4	1.8	1.4	1.7
• All	4.7	5.9	4.7	6.1	4.8	5.8

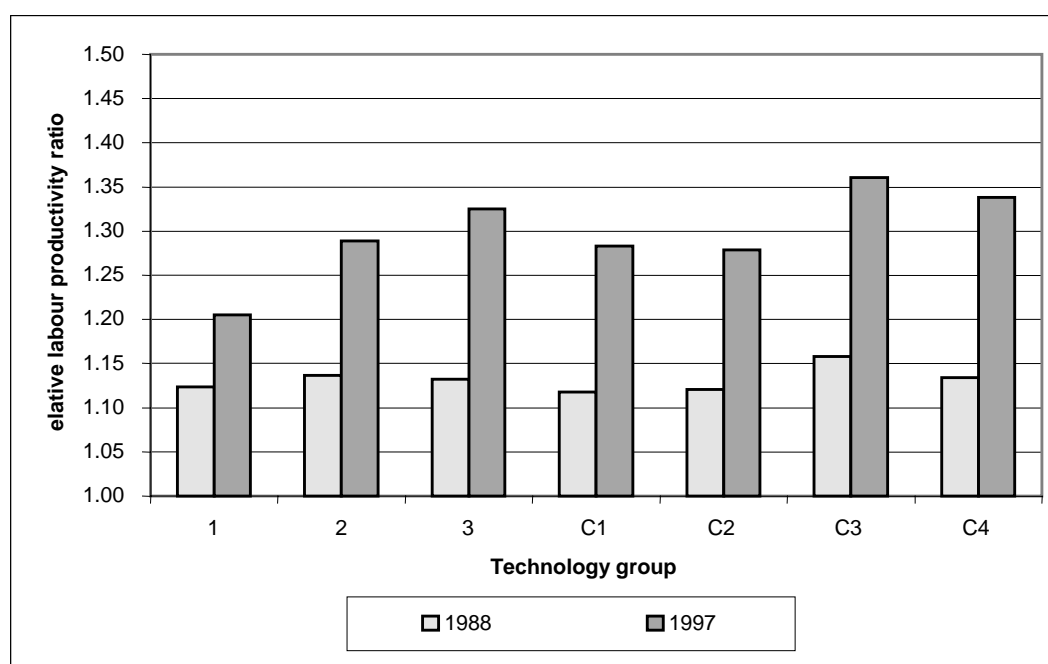

1. Differences reported in this table are statistically significant at the 5% level. In fact, most are statistically significant at the 1% level. Labour productivity is defined as total value added divided by total employees; profitability is defined as total shipments less materials less wages and salaries divided by total shipments – the price/cost margin.

Establishments in the top half of the labour productivity growth distribution are found to be more likely to be using at least one advanced technology. This result extends across all ICTs – software, hardware and communications. High-productivity growth establishments are also more likely to be using greater numbers of technologies.

Differences also exist between the fastest labour productivity growers in terms of combinations of advanced technologies used. The greatest differences are found for plants that use all three types of ICTs. A significantly higher proportion of high-productivity growers adopts all three types of ICTs than do low-productivity growers – a difference of 15 percentage points.

Finally, there are differences in the intensity of advanced technology use. Establishments with the highest growth in labour productivity adopt, on average, 5.9 advanced technologies compared to 4.7 for low-growth plants. Similar differences are found across the individual ICT groups.

Figure 3. **Relative productivity of advanced technology users and non-users, 1988 vs. 1997**

Group number	Technology group	Group number	Technology group
1	Software	C1	Software and hardware
2	Hardware	C2	Software and communications
3	Communications	C3	Hardware and communications
		C4	Software, hardware and communications

We also examine how the productivity of advanced technology users relative to non-users has evolved over time, using a classification that divides plants into users and non-users based on their status as of 1998. To do so, we calculate the ratio of the mean productivity of advanced technology users to the mean productivity of non-users of advanced technology in 1988 and 1997 and then plot this relationship in Figure 3.⁷ This is done for each of the technology groups – software, hardware, communications – and then for four sets of combinations – software and hardware (C1), software and communications (C2), hardware and communications (C3) and all three (C4). Advanced technology users have increased their productivity advantage over non-users across all technology measures, particularly when it involves the use of network communication technologies, both taken alone and in combination with other types of advanced technologies. The largest rates of increase in relative productivity occur in the network communications group; in hardware and communications; and in the use of all three ICTs. This replicates the findings of our earlier study (Baldwin, Diverty and Sabourin, 1995), which reports that the greatest gains in relative productivity in the 1980s occurred in plants that adopted advanced communications technologies, either singly or in combination with other ICTs.

7. The ratio is calculated as the sum of value added of all plants that are technology users divided by the sum of employment in a class divided by the same ratio for non-technology users.

When plants are divided at the median on the basis of profitability growth (defined as the growth in the price-cost margin)⁸ over the 1988-97 period, we also find significant differences in the incidence of advanced technology use, the numbers of technologies used and the extent to which advanced technologies from software, hardware and communications are used jointly (Table 6, column III). Plants with the highest growth in profitability adopt, on average, 20% more advanced technologies than do low-growth plants. High-profitability-growth plants adopt, on average, 5.8 advanced technologies compared to 4.8 for low-growth plants. These differences extend to incidence of use as well, with hardware and network communications technologies exhibiting the greatest differences.

When growth in market share is used to divide the sample into two parts, similar results are found. The plants that experienced the highest market-share growth also tend to be more likely to adopt more advanced technologies from each of the groups.

Multivariate analysis

Model

In this section, we use a multivariate framework to examine the connection between advanced technology use and several measures of the market performance of plants in the manufacturing sector. The performance measures are the growth in relative productivity, the relative average wage rate, relative profitability as well as the growth in market and employment share.

There are two main components to the analysis – an equation that estimates the correlates of productivity growth and one that examines the correlates of market-share growth. The regressions that were estimated were:

$$1) \text{ PRODGRTH} = \alpha_0 + \alpha_1 * \text{TECH} + \alpha_2 * \text{SIZE88} + \alpha_3 * \text{FOREIGN} + \alpha_4 * \Delta \text{CAPINT} \\ + \alpha_5 * \text{LABPROD88} + \alpha_6 * \text{R\&D} + \alpha_7 * \text{INNOV} + \alpha_8 * \text{BUS} + \\ \alpha_9 * \text{REGION}$$

$$2) \text{ SHARGRTH} = \beta_0 + \beta_1 * \text{TECH} + \beta_2 * \text{SIZE88} + \beta_3 * \text{FOREIGN} + \beta_4 * \Delta \text{CAPINT} \\ + \beta_5 * \text{LABPROD88} + \beta_5 * \Delta \text{LABPROD} + \beta_5 * \text{MKTSHR88} \\ + \beta_6 * \text{R\&D} + \beta_7 * \text{INNOV} + \beta_8 * \text{BUS} + \beta_9 * \text{REGION}$$

where *PRODGRTH* measures the growth in relative labour productivity of a plant.

SHARGRTH measures the growth in market share of a plant.

TECH MEASURES the use of advanced technologies by the establishment.

SIZE88 MEASURES OPENING-PERIOD EMPLOYMENT SIZE OF THE PLANT.

FOREIGN CAPTURES WHETHER OR NOT AN ESTABLISHMENT IS FOREIGN OWNED.

ΔCAPINT CAPTURES THE CAPITAL INTENSITY OF A PLANT THROUGH CHANGES IN PROFITABILITY.

LABPROD88 MEASURES OPENING-PERIOD LABOUR PRODUCTIVITY LEVELS.

ΔLABPROD MEASURES CHANGES IN RELATIVE LABOUR PRODUCTIVITY OVER TIME.

MKTSHR88 MEASURES OPENING-PERIOD MARKET SHARE.

R&D CAPTURES whether or not an establishment is an R&D performer.

INNOV CAPTURES VARIOUS ASPECTS OF INNOVATION IN A PLANT.

BUS CAPTURES THE EXTENT TO WHICH ADVANCED BUSINESS PRACTICES EXIST IN A PLANT.

REGION CAPTURES any regional effects.

8. Profitability is defined as value of shipments less wages and salaries less materials divided by value of shipments.

Productivity growth

The first equation examines relative productivity growth during the 1988-97 period.

Relative productivity growth is postulated to be a function of advanced technology use at the end of the period since end-period advanced technology use is taken as an indicator that the plant has learned how to work with innovative technological processes. We capture advanced technology use with a number of mutually exclusive, increasingly comprehensive and, therefore, sophisticated technology variables. Use of one type, and only one type, of the three information and communication advanced technologies – software, hardware and communications – is captured by a set of three binary technology variables. Four other variables capture the use of combinations of ICTs – software and hardware; software and communications; hardware and communications; and the most sophisticated of all, the use of all three types.

Previous work (Baldwin, Diverty and Sabourin, 1995) found that, in 1989, the use of just one particular technological group (fabrication, design and engineering, or communications) was sufficient to differentiate plants from one another in terms of performance – but also found that the plants that were combining advanced technologies from different areas were characterised by the best performance. Since we are measuring advanced technology use ten years later in 1998 and since, by the latter year, many more plants had adopted at least one advanced technology, we expect the single technology-use variables to have less effect on plant performance in the 1990s. But we hypothesise that those plants combining advanced technologies from a number of different areas will exhibit the fastest productivity growth over the 1990s.

Productivity growth is also likely to be a function of advanced technology use to the extent that advanced technology use is associated with higher capital intensity. To correct for this, the increase in a plant's relative profitability (its profit/sales ratio) is also included, since the measure of profitability should be closely correlated with capital intensity on average.

Plant size was included to capture the greater financial and informational capabilities often associated with larger establishment size. Large plants tend to invest more in new equipment and capital, which tends to lead to growth. Employment data were used to measure size.

Initial period productivity is included to allow for regression-to-the-mean. Previous work (Baldwin, 1995) and the tables presented in the first section of this paper have reported that plants tend to regress to the mean over the period.

Nationality of ownership of a plant is included since multinational firms are seen to play an important role in the global diffusion of advanced technologies (Caves, 1982). Previous work has found that labour productivity growth in foreign-controlled plants has been greater than in the domestic sector (Baldwin and Dhaliwal, 2001). The advantages of multinational enterprises are typically related to their size, expertise and financial resources. Nationality of control is captured, in this study, by a binary variable that takes a value of one if the establishment is foreign controlled, and a value of zero if the establishment is domestically controlled.

A binary variable that measures whether the plant reported that it performed R&D is also included. This is done for two reasons.

First, because of the evidence from previous studies on the effect of R&D on productivity (Lichtenberg and Siegel, 1991; Hall and Mairesse, 1995; Dilling-Hansen *et al.*, 1999), we are inherently interested in knowing whether R&D activity affects productivity performance after the technology mix has been taken into account.

Second, the inclusion of this variable is meant to reduce the fixed-effects econometric problem. The econometrics literature has spent considerable effort worrying that equations like Equation 2 will yield biased estimates of the parameters attached to the independent variables if there are omitted fixed effects at the plant level that are correlated with the included variables. Much of our previous work on the characteristics of firms suggests that this is likely to be a problem. This is because firms divide into those who are innovative and stress a large number of functional areas, such as human resources or marketing capabilities (Baldwin and Johnson, 1996, 1998, 1999), and those who do not. Since advanced technology use is likely to be highly correlated with the plant's degree of innovativeness, a regression that only employs advanced technology use will risk attributing the effect of a large number of activities to just advanced technology use. The correlation between technology use and productivity may simply reflect the fact that superior firms make greater use of new technologies and do a lot of other things as well (see McGuckin *et al.*, 1998).

In order to address this problem, we include three different variables that capture whether a plant is more innovative. The first innovativeness variable captures whether R&D is conducted either in that plant or in an associated plant on an ongoing basis. Previous work demonstrates that firms that conduct R&D on an ongoing, as opposed to an occasional, basis are more likely to be innovative (Baldwin and Hanel, 2002).

The second is a variable that measures the importance attributed to a number of strategies that capture aspects of innovation that are different from a plant's R&D focus. On the technology survey, plant managers rated the importance of "developing new products, entering new markets, using new materials, giving ongoing technical training, and using teams" on a five-point Likert scale from 1 for "low importance" to 5 for "high importance". Variants of these questions have been used previously in the Growing Small and Medium Sized Enterprise Survey and the Survey of Operating and Financial Practices to distinguish between more and less innovative firms (Baldwin, Chandler *et al.*, 1994; Johnson, Baldwin and Hinchley, 1997). The questions used here to measure the innovation stance of the firm do so in two ways. First, this phenomenon is captured directly with the question on whether new products have been introduced. Second, it is captured indirectly via an examination of human resource, marketing and production strategies. Innovation and a training strategy are closely related (Baldwin, 1999): focusing on new materials involves innovation; placing a stress on new markets is an essential part of an innovation strategy. The variable included in the estimated regression is the average of the response to the five survey questions listed above.

The third innovation-related variable measures the emphasis given to a set of advanced business practices that were found elsewhere to be closely associated with the adoption of advanced technologies (Baldwin, Sabourin and West, 1999). These practices include "cross-functional design teams, concurrent engineering, continuous improvement (*i.e.* TQM), benchmarking, plant certification (*i.e.* ISO 9000), certification of suppliers, just-in-time inventory control, statistical process control, electronic work order management, process simulation, distribution resource planning and quality function deployment". Many of these practices are required to make the best use of advanced technologies. For example, concurrent engineering complements CAD systems and enables plants to better exploit the capabilities of these new technologies. Use of these practices then allows us to distinguish between those plants that are better managed and those that are not. For the statistical analysis, we make use of a variable that measures the number of these practices used in any particular plant. In addition, binary variables were included to test whether the geographic environment matters.

Market-share growth

The second equation examines the correlates of growth in market share. Growth in market share is postulated to depend on factors that give a firm an advantage over its competitors. Growth in market share

is posited to be a function of both the advantages in labour productivity experienced at the beginning of the period and its growth over the period. In our formulation, growth in relative labour productivity is a proxy for a host of factors that are related to technical efficiency, changes in capital intensity, and other competencies in a firm, ranging from management capabilities to human resource strategies such as training.

Although we already have included advanced technology use in the labour-productivity equation, we also include advanced technology use in the market-share equation to test whether there is an effect of advanced technology on market-share growth that is separate from its effect on the growth in relative labour productivity. Advanced technology use not only allows relative cost gains that are reflected in lower prices, it also improves the flexibility in the production process and the quality of products produced (Baldwin, Sabourin and Rafiqzaman, 1996; Baldwin, Sabourin and West, 1999). As such, it might be expected to have an independent effect on growth in market share independent of its effect on measured labour productivity.

The other variables were essentially the same as were used in the growth in the relative productivity model, except that we included opening-period market share so as to allow for regression-to-the-mean. Baldwin (1995) outlines the inexorable changes that have occurred in the Canadian manufacturing sector in the 1970s in most industries as small plants gained market share and large plants lost market share. The data in Table 3 demonstrate that the same process was taking place during the late 1980s and early 1990s.

Empirical results

The results of the OLS regression that models several different measures of market performance as a function of advanced technology use are presented in Table 7. Since the data are taken from a survey that randomly sampled the population, weighted estimates are provided. All regressions are estimated against an excluded plant that is Canadian-owned, has not adopted ICTs, does not perform R&D, and is in the Atlantic region.

Growth in productivity

Growth in relative labour productivity is positively and significantly related to advanced technology use (column 1, Table 7). Plants that have managed to adopt advanced technology by the end of the period have higher productivity growth over the period than those that have not. But it is a particular type of technology use that is associated with the growth in relative labour productivity. Establishments that had adopted only network communications technology were significantly more likely to have higher productivity growth than those that did not. But the real gains came from the joint adoption of all three types of technology – software, hardware and network communications. These results are significant at the 1% level if capital intensity is not included as an explanatory variable (column 2); and at 5% if it is included (column 1). Regressions were also run (but not reported here) using numbers of advanced technologies adopted, instead of incidence of adoption, as the independent variables. Similar results were found. Plants that made greater use of advanced technologies in the late 1990s experienced relatively faster productivity growth during the previous decade. This relationship is particularly strong for plants that adopted network communications technologies.

Significantly higher growth in labour productivity is found to be associated with foreign-controlled establishments. This finding occurs despite the inclusion of size, R&D performance and technology usage. It is sometimes suggested that it is these variables that primarily determine the labour productivity advantages of foreign-controlled plants. However, their inclusion here, along with the significant

coefficient attached to foreign-controlled plants, indicate that there are still other unmeasured characteristics that give multinationals a productivity advantage.

The coefficient attached to plant size is positive but not significant. The difference in productivity growth between large and small plants in Canada during the early 1990s accords with previous studies dealing with the 1970s and 1980s (Baldwin, 1998; Baldwin and Dhaliwal, 2001). If nationality of ownership is omitted from the regression, however, the coefficient on plant size becomes significant at the 5% level. This suggests a strong link between size and nationality of ownership as it relates to productivity growth. Foreign-controlled establishments tend to be larger than domestic-controlled establishments. But after controlling for nationality of ownership differences, no size advantages are found.

The coefficient on the starting-period productivity variable is negative and highly significant. There is regression-to-the-mean in relative productivity. Plants that started the period with a high relative labour productivity saw their relative labour productivity decline. Equivalently, those plants that were below average in terms of relative labour productivity at the start of the period saw their productivity increase relative to their compatriots.

*** Statistically significant at the 1% level; ** at the 5% level; * at the 10% level.

There is a large, significant effect of the growth in capital intensity on the growth in relative labour productivity. Because there is some overlap in the definitions of labour productivity and profitability, we remove this variable from the estimation to see whether doing so affects the estimated parameters associated with the advanced technology variables (Table 7, column 2). It does not.

Neither R&D performance nor the other variables (business strategy and business practices) are significant determinants of a plant's relative productivity growth. This suggests that the fixed effects captured by these variables do not bias the estimated impact of technology on productivity growth.

Finally, regional location does not have a consistently significant effect on labour productivity growth – although it should be noted that the omitted region (the Atlantic Provinces) has a slightly superior performance to the other regions. This is consistent with a regression-to-the-mean effect, since this region lags behind the other regions in labour productivity (Sabourin, 2001).⁹

Growth in market share

Labour productivity at the start of the period and growth in relative labour productivity over the period are both positive and highly significant factors contributing to market-share growth (columns 3 and 4, Table 7).

However, once the effects of relative productivity growth on market share are taken into account, growth in market share is not related to advanced technology use. It is related to whether a plant benefits from the performance of R&D and to whether a set of technology-related business strategies are being pursued. If the innovation-related variables (R&D, business practices and business strategies) are removed – in an unreported regression – then the most sophisticated use of technology variable (the use of all three technologies) becomes significant, as does the use of software and communications technologies by themselves. Establishments that adopt all three types of ICT are significantly more likely to increase their market share but only when the other innovative variables are removed from the regression. In addition, establishments that adopt communication technologies are also more likely to increase their market share. This accords with our earlier finding that communication technology use at the end of the 1980s was most closely associated with superior performance during that decade (Baldwin, Diverty and Sabourin, 1995).

What conclusions can be drawn from this? In previous work, we have found that some firms adopt a very different innovation profile (Baldwin and Johnson, 1996, 1998, 1999): they perform R&D; they stress a number of advanced management practices; *and* they are comprehensive advanced technology users. For this, they are rewarded with growth in market share. Comprehensive technology use matters, but as part of a package of activities.

As with relative labour productivity, there is a regression-to-the-mean process at work in changes in market share. Plants that are larger in 1988 generally lost market share. However, this result is not statistically significant. Foreign-controlled plants are gaining market share.

There are no significant regional effects. This result implies that there have been very few changes in the relative importance of plants within industries at the regional level – that the geographic distribution of employment has been relatively constant.¹⁰

9. There were no differences in these equations across industries.

10. For more on changing regional distributions, see Baldwin and Brown (2001).

In summary, advanced technology use emerges from the multivariate analysis as having a close relationship to the growth in relative labour productivity. Plants that manage to incorporate advanced technologies, to do so more intensively, and to combine advanced technologies across more functional groups, also grew in terms of relative labour productivity. In turn, growth in relative labour productivity is translated into growth in market share.

It should be noted that advanced technology use not only had an indirect effect on growth in market share via relative productivity growth, it also had a direct effect, albeit in conjunction with innovation in general. This is probably because advanced technologies, along with a general inclination to innovate, increase the flexibility of firms and hence their ability to respond quickly to customer needs, thereby enhancing their market shares.

Conclusion

Our understanding of the amount and type of dynamics in the firm population has improved as a result of the development of longitudinal databases that allow us to measure the entry of new firms, and the exit of old ones, and how incumbents change market position as the result of growth and decline. While these databases allow us to measure some aspects of the effects of competition, they do not easily allow us to understand the underlying factors that are generating the change. For this, we need more detail on the underlying characteristics of firms and their plants. This paper has used data on one such characteristic – the incidence of use of advanced technologies – as well as the extent to which plants were pursuing a general strategy of innovation.

One question that is often posed is the extent to which ICTs have an effect on the amount of change that is occurring. This paper has addressed this question by examining whether plants with different growth paths made different use of advanced technologies. Examining differences in success across plants reveals which sets of advanced technologies are more appropriate than others. All plants have the same technological capabilities open to them at any point in time, but only a subset of the population chooses to adopt ICTs. By examining which plants and which technologies were more closely associated with success, we isolate which of the technological paths were revealed by the competitive process to be the most successful.

We find that the adoption of many of the ICTs was associated with greater growth in labour productivity and market share during the period 1988 to 1997.¹¹ This finding replicates the results of an earlier paper that examined the relationship between plant performance in the 1980s and advanced technology use (Baldwin, Diverty and Sabourin, 1995). This confirms our view that the adoption of ICTs is one of the keys to growth. And this growth is associated with improvements in labour productivity.

We have also found that communications technologies play a special role in growth. ICTs are built around the capabilities of computers. Computer-assisted machines not only allow for precision cutting, shaping and forming, computer technologies permit the acquisition of large amounts of information that in turn permit monitoring, evaluation and rapid adaptation to changing circumstances. The capabilities of the new technologies have been referred to as bringing about the “soft-manufacturing revolution” (Bylinsky, 1994). The new advanced technologies permit the advantages of machines to be effectively combined with human cognitive capabilities. It is in this area that advanced technology adoption appears from the evidence adduced here to have had the greatest impact.

11. Weaker effects are also found for ICT adoption on relative wage rate growth and relative profitability growth.

Several caveats to the results summarised above are, however, necessary. Our results do not show that simply purchasing advanced technologies necessarily leads to success. We have shown that those plants that successfully implement ICTs (those who report that they possess such equipment) do better than others. However, implementation requires a number of skills: it requires a human-resource strategy to develop the necessary worker skills (Baldwin, 1999, 2000); and it requires that firms overcome financing problems associated with acquiring new and untried technologies (Baldwin and Lin, 2001). Innovation, even on the technical side, is often accompanied by the development of best practices in quality control and engineering (Baldwin and Sabourin, 2000).

In this paper, we have focused on only one characteristic of manufacturing plants – their technological sophistication. However, we recognise that plants rarely distinguish themselves from others in only one dimension. Baldwin and Johnson (1996, 1998) demonstrate that innovative and non-innovative firms differ in a number of dimensions simultaneously – in terms of the emphasis placed on marketing, human resources, financing and technological developments. Technology is just one part of the puzzle that creates a successful firm. That being said, it is a key piece, as this paper has shown. Plants that adopt advanced technologies become more productive and grow more quickly. That they have to master a number of skills to be successful does not subtract from the central importance of mastering a way to successfully introduce ICTs into the business operations of manufacturing plants.
